Currency Investing Throughout Recent Centuries

Abstract

The literature on currency investing, such as the carry trade, typically bases its analysis on the floating exchange rate period since 1973. I analyze risk and return characteristics of currency investing across 21 currencies over an extended period with data that spans more than two centuries and reach back as far as 1788. In addition to using short-term interest rate as the investment vehicle, I also investigate using long-term bonds. I find that carry trade return would have been surprisingly robust throughout history and robust to using long-term bonds. Examination of other currency investment strategies fails to find a statistically significant momentum effect or reversal effect. Moreover, cross-currency yield-curve flattening trade produces robust returns with Sharpe ratio double that of the carry trade. These results help better understand the nature and the source of premia among currency investments.

1 Introduction

A rapidly growing literature in finance is uncovering a variety of ways in which currency investments produce abnormally high returns. The most often studied strategy is the currency carry trade, which goes long currencies with high interest rates and goes short currencies with low interest rates. Lustig, Roussanov, and Verdelhan (2014) introduce a version of the carry trade called the 'dollar carry trade', which focuses on the carry trade of a single currency and has also been shown to produce abnormally high returns. A series of papers by Menkhoff, Sarno, Schmeling, and Schrimpf (2012a, 2017) and Asness, Moskowitz, and Pedersen (2013) document the momentum effect and the reversal effect in currency markets. Ang and Chen (2017) use the slope of the yield curve, while Menkhoff, Sarno, Schmeling, and Schrimpf (2012b) use the volatility of exchange rates to construct additional strategies that produce high returns in currency investments.

Common across these studies is that they only use a limited history of data. Some studies begin in 1973 at the end of the Bretton Woods system when major currencies began to float freely. While the underlying economics might differ under fixed versus floating currency exchange regimes, there is no ex-ante reason to remove these observations based on exchange regimes. The most common starting point for these studies is the early 1980s, when data on forward exchange rates, which embeds short-term interest rates, become available from commonly accessed data providers such as Datastream (see for example, Koijen, Moskowitz, Pedersen and Vrugt; 2018 and Bekaert and Panayotov; 2018). A notable exception is Accominotti, Cen, Chambers, and Marsh (2019), who extend forward exchange rate data back to 1919 but only study the carry trade. Using forward exchange rate data has the advantage that it accounts for transaction costs from the perspective of a hypothetical arbitrageur. However, an arbitrageur's perspective is not the correct perspective for understanding the underlying economic source of risk premia in currency investments. In fact, abstracting away from implementability concerns and using historical interest rates rather than forward exchange rates allows for a broader study of the historical performance of currency investing.

I develop a comprehensive historical view of returns on currency investing that spans over two centuries and reach back as far as 1788. Admittedly, this is purely a historical thought experiment. In order to conduct this study, I abstract away fully from various implementability concerns. In addition to transaction costs, there would have been binding constraints that would have prevented international movement of capital. Furthermore, a wide enough cross-section of historical short-term interest rates (short rates) is only available from around 1854. Rather than an experiment where capital is stored at the short rate, an alternative experiment is one where capital is invested in a different asset, such as longer-term bonds (long bonds). This alternative allows for an additional robustness test and allows for even longer historical data. Recent study by Lustig, Stathopoulos, and Verdelhan (2019) also investigate the carry trade using long bonds, but their focus is on examining the robustness of carry trade to using longer maturity bonds. Unfortunately, returns on long bonds must be inferred from changes in recorded yields and may reflect additional risk premia for exposures to sovereign default risk or other economic sources of premia. Furthermore, most studies in the literature take the perspective of an investor in a 'home currency'. However, no single currency was dominant across all of history that could serve as a 'home', so my experimental design needs to be truly 'base-currency neutral'.

In this paper, I construct an extended historical dataset of foreign exchange rates, short-term interest rates, and long-term interest rates and design an experiment that overcomes these technical difficulties. Rather than creating a dataset from the perspective of a US investor allocating all funds into foreign investments, I include investments in the US as a trivial zero excess return investment. By including the option to invest in the home currency, this study is made base-currency neutral. Moreover, with minor assumptions, I can construct returns on long bonds by estimating the capital gains of holding longer-term bonds from changes in bond yields. In total, I have data covering upwards of 21 currencies across 230 years. With this dataset, I construct currency investment portfolios based on various strategies and run panel regression analysis to examine their statistical significance.

This longer historical perspective provides useful insights. First, the carry trade is surprisingly robust throughout history. In contrast to the findings in Lustig, Stathopoulos, and Verdelhan (2019), the carry trade portfolio is robust to using long bonds instead of short rates, and the carry trade would have continued to produce abnormally high returns over longer history. The carry trade returns, using either the short rates or the long bonds, are lower during fixed exchange rate regimes, such as under the Gold Standard or under the Bretton Woods Agreement. However, since foreign exchange rate volatility was significantly lower, it amounts to high Sharpe ratios and high risk-adjusted returns for the carry trade during these periods. The point in time when the carry trade failed to produce high return is during the economic recovery periods following the World Wars, but otherwise, the carry trade would have produced high returns going all the way back to 1788. In fact, the dollar carry trade, which focuses on investments in the US dollar according to the US interest rate relative to the global average rate, would have also exhibited qualitatively similar patterns. This trade would have also produced robust positive returns throughout history, except for during the economic recovery following the World Wars and one additional period around the US Civil War period. Panel regressions confirm these results.

This historical perspective also offers additional insights. The currency momentum effect seems to be robust to using a longer history, unless the sample goes back far enough in history. Based on data starting in 1788, currency momentum trade would have produced positive returns in the latter half of the sample, but not throughout the entire sample. Panel regressions also fail to detect a currency momentum effect. For currency reversals, the effect only seems to exist within the sample studied by others. Outside the most recent period after the break-down of the Bretton Woods Agreement, there is no evidence of currency reversal trade producing positive abnormal returns. These results suggest that data-snooping bias could be an issue unless there exists time-varying underlying mechanism at work that drives these effects.

In addition to providing out-of-sample examinations of currency investment strategies, this extended dataset can help uncover new strategies that offer abnormally high returns. Since the extended data includes long-term interest rates besides short-term interest rates, the term spread, or the slope of the yield curve, can be used to construct portfolios. An examination that extends the studies by Ang and Chen (2017) and Lustig, Stathopoulos, and Verdelhan (2019) of currency predictability using the slope of the yield curve suggests constructing a 'long-short spread' portfolio that goes long long-term bonds and goes short short-term rates when the term spread in a currency is high relative to the term spreads of other currencies. This strategy is essentially cross-currency yield-curve flattening trade and provides Sharpe ratios that are double that of the carry trade and is robust across all periods. Explaining the source of risk premia for strategies like this is left for future research.

The study of the carry trade is related to an extensive literature in international finance that documents violations of uncovered interest rate parity (UIP). Hassan and Mano (2019) offer a comprehensive decomposition relating the two sets of findings. The earliest works that examine violations of UIP, such as Hansen and Hodrick (1980) and Fama (1984), have focused on the period after 1973, following the break down of the Bretton Woods Agreement and the end of the fixed exchange rate regime. Hansen and Hodrick (1980) also examined the violation of UIP in an earlier post

World War I period from January 1922 to July 1926, but they also limited their study to a period of flexible exchange rate regime. While there are economic reasons to focus on periods with flexible exchange rate regimes, currency investments could still be a viable strategy under fixed exchange rate regimes, and the same pricing mechanism ought to still hold in either regime. Lothian and Taylor (1996) and Lothian and Wu (2011), do examine violations of purchasing power parity (PPP) and UIP, respectively, for a period spanning two centuries beginning in 1791 and ending in 1990. However, they only examine two currency pairs (GBP vs. USD and GBP vs. FRF). Relative to these studies, this paper examines the returns on currency investing over an extended period, spanning a variety of regimes, across a broader cross-section of currencies, and based on a variety of currency investment strategies.

More recent works examine currency investments by constructing returns on currency portfolios formed from a broad cross-section of currencies, rather than select pairs of currencies. Currency portfolios are formed according to various signals, such as interest rates and past currency appreciations, to generate the 'carry trade' or the 'momentum trade'. Lustig and Verdelhan (2007) and Lustig, Roussanov, and Verdelhan (2011) examine currency portfolio returns starting in 1955 and 1983, respectively, and find that two principal factors, a carry trade factor and a 'dollar factor', can summarize much of currency investment returns. There is an extensive literature that tries to explain the source of risk premia to the carry trade, such as Burnside, Eichenbaum, Kleshchelski, and Rebelo (2011), but the vast majority continues to focus on the floating exchange rate period after the 1970s. Two papers closest to mine are Doskov and Swinkels (2015) and Accominotti, Cen, Chambers, and Marsh (2019), who examine the carry trade beginning in 1900 and 1919, respectively. Doskov and Swinkels (2015) use the annual-frequency database by Dimson, Stauton, and Marsh (2013) to extend their sample, whereas Accominotti, Cen, Chambers, and Marsh

(2019) use daily-frequency data from forward market in London. Whereas these two papers focus on the carry trade, to the best of my knowledge, this paper is the first to examine other types of currency investment portfolios and spans an additional century of data.

There is also a line of literature in other areas of finance that investigates the robustness of other predictability results using an extended historical data. Schwert (1990) examines the predictability of the US stock market using macroeconomic variables going back to 1889. More recently, Golez and Koudijs (2018) investigate the robustness of aggregate stock market predictability using the dividend-to-price ratio as far back as 1629. In the literature of cross-sectional predictability, Davis, Fama, and French (2000) examine the robustness of the predictive ability of book-to-market using data going back to 1929. Similarly, recent work by Linnainmaa and Roberts (2018) reexamines the cross-sectional predictability using accounting variables using data starting from 1918. Jordà, Knoll, Kuvshinov, Schularick, and Taylor (2019) examine historical returns of all major asset classes from 16 economies going back to 1870. This paper follows this rich tradition in the literature of conducting out-of-sample tests of empirical findings by going further back in history.

This article is organized as follows. In Section 2, I discuss the methodology I used to allow the long bonds to be the investment asset and provide some details of the portfolio formation and regression methodology used in my analysis. In Section 3 describes the data. In Section 4, I report historical returns on the carry trade over the extended data sample and show robustness with respect to various specifications of the analysis. In Section 5, I extend the analysis to examine the robustness of other currency investment strategies over recent centuries. Finally, Section 6 concludes.

2 Returns on Currency Investing

Every currency investment portfolio studied in the finance literature involves investments in the short rates. When I examine currency investments reaching further back in history, I can obtain a more extensive data sample if I consider investments in other types of foreign assets. I begin in this section by generalizing the framework used in the literature to allow for foreign investments in assets other than the short rates. By using other investments, such as long bonds, I can increase my data sample quite substantially in my empirical analysis. However, computation of returns on long bonds requires an extra approximation, which induces some noise in the study.

2.1 Foreign Exchange Returns

For each currency, I obtain the end-of-period exchange rate in terms of the dollar price of one unit of foreign currency, which I denote as S_t^i. I define the gross foreign exchange (FX) return on currency i over the next period,[1] denoted $R_{t+1}^{FX,i}$, as

$$R_{t+1}^{FX,i} = \frac{S_{t+1}^i}{S_t^i}. \tag{1}$$

Given a gross investment return in a foreign currency, R_{t+1}^i, I define total investment return with currency appreciation, denoted $R_{t+1}^{Tot,i}$, as

$$R_{t+1}^{Tot,i} = \frac{S_{t+1}^i}{S_t^i} R_{t+1}^i. \tag{2}$$

The literature typically defines the excess foreign exchange return on currency i, denoted Π_{t+1}^i, as

$$\Pi_{t+1}^i = \frac{S_{t+1}^i}{S_t^i} \frac{R_{t+1}^i}{R_{t+1}^{US}}. \tag{3}$$

[1] The use of 'gross returns' to denote the pay-offs of a one-unit investment follows convention established in Cochrane (2000).

This return is the future value of taking one USD to purchase $1/S_t^i$ units of foreign currency i and investing in an asset with a total return of R_{t+1}^i, relative to the future value from an equivalent investment made in the US with a return of R_{t+1}^{US}. Following the literature, the US is treated as the 'home' currency for now, and robustness to changing the base currency is addressed later. In logarithmic term, excess foreign exchange return is:

$$\pi_{t+1}^i = (s_{t+1}^i - s_t^i) + (r_t^i - r_t^{US}), \tag{4}$$

where $s_{t+1}^i - s_t^i$ is the log currency appreciation rate and $r_t^i - r_t^{US}$ is the difference in log returns of the investment asset.

The existing literature uses the short rates as investment returns, R_{t+1}^i, and run their analysis at monthly or annual frequency data. In cases where forward rates exist and covered interest rate parity can be expected to hold, log excess foreign exchange return can be rewritten as

$$\pi_{t+1}^i = f_{t+1}^i - s_t^i, \tag{5}$$

where f_{t+1}^i is the log one-period forward foreign exchange rate.

The literature often directly examine this difference between the forward rate and the spot rate since the forward rate implicitly embeds the short-term interest rate (Hansen and Hodrick, 1980; Fama, 1984). Using the forward rate implicitly assumes that covered interest rate parity holds, and has the advantage that daily frequency data is available for computing volatility (Menkhoff, Sarno, Schmeling, and Schrimpf, 2012b; Accominotti, Cen, Chambers, and March, 2019) and bid-ask spread data is available for estimating transaction costs. Accominotti, Cen, Chambers, and March (2019) extend this approach and obtain spot and forward exchange market data extending back to December 1919 across 19 currencies. Similarly, Doskov and Swinkels (2015) obtain short rate data extending back to 1901 across 20 currencies.

Lothian and Wu (2011) are able to extend the short rate data back to 1800, but only for three currencies.

To obtain longer historical data across a broader set of currencies, I recognize that the investment asset used for R^i_{t+1} does not need to be restricted to short rates. For instance, in the literature testing the validity of Purchasing Power Parity (PPP), the investment asset is a basket of real assets. In my study, I use the return on longer-maturity bonds as the investment return. There are various disadvantages to using bond returns, such as the fact that bond returns might have additional premia embedded in them for term structure risk, sovereign default risk, or illiquidity. Moreover, I generally do not observe bond returns but have to estimate them from recorded yields.[2] Nevertheless, I accept these disadvantages and examine currency investment portfolios using long bonds to extend the data sample.

2.2 Approximation of Bond Returns

In my dataset, I generally observe the yield, $y_t^{(n)}$, on some n-period coupon paying bond, but I do not directly observe the returns on bond investments.[3] In some instances, I observe perpetual bonds with $n = \infty$, as in the case of the Consols issued by the Bank of England. If an investor holds a bond over a single period from time t to time $t+1$, the return on the bond is generally not equal to the bond yield because there will be capital gains associated with holding a longer-term bond over a shorter time interval. I begin by approximating the total bond return from yields observed at times t and $t+1$.

[2] Some papers, such as Lothian and Wu (2011), ignore the difference between bond returns and bond yields and proceed to use bond yields itself as an approximation of bond returns. This method ignores the capital gains component of returns, which can be substantial.

[3] My data providers sometimes observe the actual bond prices, $P_t^{(n)}$, but only record the yields inferred from the prices.

To simplify my notations, I define the bond present value (BPV), in terms of percentage of par, of a n-period $c\%$ coupon paying bond at discount rate y as:

$$BPV(n, c, y) \stackrel{def}{=} \frac{c}{(1+y)} + \cdots + \frac{c+1}{(1+y)^n}. \tag{6}$$

This function has the well-known property that $BPV(\cdot) = 1$ whenever $c = y$ (Malkiel, 1962). In the special case of a perpetual bond, $BPV(\infty, c, y) = c/y$.[4]

At time t, the price of the bond is

$$P_t^{(n)} = BPV(n, c, y_t^{(n)}) = \frac{c}{(1+y_t^{(n)})} + \cdots + \frac{c+1}{(1+y_t^{(n)})^n}. \tag{7}$$

However, at time $t+1$, the ex-coupon price of this bond, which is now an $n-1$ period bond is

$$P_{t+1}^{(n-1)} = \frac{c}{(1+y_{t+1}^{(n-1)})} + \cdots + \frac{c+1}{(1+y_{t+1}^{(n-1)})^{n-1}}. \tag{8}$$

By adding the coupon back in, the cum-coupon value can be rewritten as:

$$\begin{aligned} P_{t+1}^{(n-1)} + c &= c + \frac{c}{(1+y_{t+1}^{(n-1)})} + \cdots + \frac{c+1}{(1+y_{t+1}^{(n-1)})^{n-1}} \\ &= BPV(n, c, y_{t+1}^{(n-1)})(1+y_{t+1}^{(n-1)}). \end{aligned} \tag{9}$$

Therefore, the total gross return of this bond over time t and $t+1$ is

$$R_{t+1} = \frac{P_{t+1}^{(n-1)} + c}{P_t^{(n)}} = \frac{BPV(n, c, y_{t+1}^{(n-1)})}{BPV(n, c, y_t^{(n)})}(1+y_{t+1}^{(n-1)}). \tag{10}$$

In the special case of a perpetual bond, the total gross return reduces to

$$R_{t+1} = 1 + \underbrace{\left(\frac{1/y_{t+1}^{\infty}}{1/y_t^{\infty}} - 1\right)}_{\text{capital gains}} + \underbrace{y_t}_{\text{yield}}. \tag{11}$$

In this case, the first term, $\frac{1/y_{t+1}}{1/y_t} - 1$, is the capital gains of holding a perpetual bond and the second term, y_t, is the single period yield of the bond.

[4] Due to this relation, yields are inferred from perpetual bond prices using $y_t = c/P_t$.

Since most of my data is not based on perpetual bonds, I estimate the total bond returns by making two assumptions.[5] First, I assume that there exists a hypothetical par bond at time t with coupon, $c = y_t^{(n)}$. Second, I assume that yield curves at the longer-maturities are flat, such that the $n-1$ period yield is equal to the n period yield: $y_{t+1}^{(n-1)} = y_{t+1}^{(n)}$. With these two assumptions, I can drop the $n-1$ and n superscripts and equation (9) becomes

$$R_{t+1} = BPV(n, y_t, y_{t+1})(1 + y_{t+1}). \tag{12}$$

With some manipulations and using the fact that $BPV(n, y_{t+1}, y_{t+1}) = 1$, the total gross return on the bond, R_{t+1}, can now be rewritten as

$$R_{t+1} = 1 + \underbrace{(BPV(n, y_t, y_{t+1}) - 1)}_{\text{capital gains}} + \underbrace{y_t}_{\text{yield}} + \eta_{t+1}, \tag{13}$$

where $\eta_{t+1} = \frac{y_{t+1} - y_t}{(1+y_{t+1})^n}$. As with a perpetual bond, the first term $(BPV(n, y_t, y_{t+1}) - 1)$ is the capital gains of holding a par bond over a single period, and y_t is the single period yield of the bond. The additional term, η_{t+1}, appears due to the assumption I made equating the yields of $n-1$ and n period bonds, and this term disappears as $n \to \infty$.

2.3 Base Currency

In the formulation presented in Section 2.1, the base currency is denominated in terms of the US dollar (USD). I construct the empirical design such that it is base-currency neutral (see Ang and Chen (2017) and Bekaert and Panayotov (2017) for a similar treatment). For my analysis, it is particularly important not to have my empirical design be anchored to any single currency since no one currency was a

[5] In contrast, Lustig, Stathopoulos, and Verdelhan (2019) assume that long bond yields reflect yields on hypothetical zero-coupon perpetual bonds.

dominant currency throughout my entire sample that goes back as far as 1788. In fact, the US dollar did not even exist until the Coinage Act of 1792.[6]

However, I can easily convert to any other base currency, FX*, with a gross investment return of R_t^*. Suppose that $S_t^{i,*}$ denotes the FX* price of one unit of foreign currency. Then total gross investment return in terms of FX* is

$$R_{t+1}^{Tot*,i} = \frac{S_{t+1}^{i,*}}{S_t^{i,*}} R_t^i. \tag{14}$$

Assuming that cross-currency arbitrage holds, such that $S_t^{i,*} = S_t^i / S_t^*$, the total investment return can be rewritten as:

$$R_{t+1}^{Tot*,i} = \frac{S_{t+1}^i / S_{t+1}^*}{S_t^i / S_t^*} \frac{R_t^i}{R_t^*} = \frac{R_{t+1}^{Tot,i}}{R_{t+1}^{Tot,*}}. \tag{15}$$

In log-terms, this is simply,

$$r_{t+1}^{Tot*,i} = r_{t+1}^{Tot,i} - r_{t+1}^{Tot,*}. \tag{16}$$

Hence, converting a US dollar return to any other currency is simply a matter of subtracting off a constant, $r_{t+1}^{Tot,*}$, at each point in time. Empirically, this term is absorbed by time fixed effects in a panel regression.

Moreover, this empirical design allows me to leave the US dollar in my sample as a data point, rather than remove it altogether as it is often done in the literature.[7] In the literature, the term 'dollar-neutral' does not mean that the US dollar is given equal footing as other currencies, but rather the US dollar is removed entirely from the analysis. Specifically, the US dollar remains in my sample as the trivial investment with the gross return of $R_{t+1}^{US} = 1$ and excess return of $\Pi_{t+1}^{US} = 1$. In this

[6] Prior to the introduction of the US dollar, my data provider uses the equivalent Pennsylvania Shilling to fill the data.

[7] Ang and Chen (2017) and Koijen, Moskowitz, Pedersen, and Vrugt (2018) also includes the US dollar as an investment vehicle in their studies.

empirical setup, the option to invest in the US is retained to maintain symmetry across all currencies. This way, if I was to change the base currency, the option to invest in the US dollar by a foreigner is maintained.

2.4 Equal-Weighted and Signal-Weighted Portfolio Returns

Returns on currency investment portfolios are constructed by varying the weights, $\omega_{t,i}$, on currency i according to some observable signal, $x_{t,i}$, at time t. Portfolios that capture a variety of currency investment strategies, such as the carry trade, momentum strategy, and value investing, are constructed by varying the signal. The gross return at time $t+1$ on a portfolio, P, is denoted:

$$\Pi^P_{t+1} = \sum_i \omega_{t,i} \Pi^i_{t+1}. \tag{17}$$

Equal-weighted long side portfolios use $\omega_{t,i} = \frac{1}{n^L_t}$, for an integer n^L_t equal to the number of currencies in the long portfolio, if the currency is in the portfolio and zero otherwise. A typical carry-trade includes currencies with the highest one-third of interest rates. Similarly, equal-weighted short side portfolio uses $\omega_{t,i} = \frac{-1}{n^S_t}$, for an integer n^S_t equal to the number of currencies in the short portfolio. In all cases, I maintain $n^L_t = n^S_t$ for all t. Note that weights sum to positive (negative) one for long-side (short-side) portfolios. Returns on long-side portfolios are compared to returns on equal-weighted portfolios that simply invests evenly across all currencies.[8] Alternatively, long-short portfolios capture the difference in returns between long-side portfolios and short-side portfolios.

While equal-weighted portfolios are often studied in the literature and used in practice, these portfolios are not particularly conducive for relating them to formal

[8] It is more common to use returns in excess of the short rate of the base currency, but using an even investment across all currencies makes the benchmark currency-neutral.

statistical analysis. In fact, portfolios need not be equal-weighted. As an alternative, I study signal-weighted portfolios where portfolio weights, $\omega_{t,i}$, maintain the property that they are a function of some signal, $x_{t,i}$ and long (short) portfolios maintain the property that the weights sum to positive (negative) one. These signal-weighted portfolios have a natural mapping to regressions.[9] Ang and Chen (2017), Menkhoff, Sarno, Schmeling, and Schrimpf (2017), and Hassan and Mano (2019) also study portfolios using weights that depend on the strength of the signals.

Given a signal, $x_{t,i}$, define cross-sectionally demeaned signal as $x^m_{t,i} = x_{t,i} - \bar{x}_t$, where $\bar{x}_t$ is the cross-sectional average of $x_{t,i}$ across i at time t. I define a signal-weighted long-short portfolio as the portfolio with the weights such that, $\omega_{t,i} = x^m_{t,i}/k_t$, where k_t is the average mean deviation of $x_{t,i}$ for those greater than the cross-sectional average $\bar{x}_t$. By construction, weights on long-short signal-weighted portfolios sum to zero. Similar to equal-weighted portfolios, signal-weighted long (short) portfolios take only the positive (negative) weights and maintain that weights sum to positive (negative) one.

Cross-sectionally demeaned signal, $x^m_{t,i}$, has the advantage that it is easily related to well-known regressions because they are mean-zero at each point in time, t. For example, typical ordinary least squares (OLS) panel regression of gross currency investment returns, Π^i_{t+1}, on cross-sectionally demeaned signal, $x^m_{t,i}$, has the regression estimate for coefficient, β^{Panel}, of

$$\hat{\beta}^{\text{Panel}} = \frac{1}{SSx} \sum_{t,i} x^m_{t,i} \Pi^i_{t+1} = \frac{1}{SSx} \sum_t \sum_i x^m_{t,i} \Pi^i_{t+1}, \tag{18}$$

where $SSx = \sum_{t,i} (x^m_{t,i})^2$. Comparing this expression to Equation (17), one can see that the average return on a signal-weighted portfolio is proportional to the regression

[9] Fama (1976) provides a discussion of the interpretation of Fama and MacBeth (1973) regressions as portfolio returns, while Hassan and Mano (2019) a provide a decomposition of portfolio returns into regressions in the context of currency investments.

coefficient from a panel regression, upto a time-varying scalar, k_t.[10] Similarly, oft used Fama-MacBeth regression in finance has the regression coefficient, β^{FM}, with an estimate of $\hat{\beta}^{\text{FM}} = \frac{1}{T}\sum_t \hat{\beta}^t$, where for each t,

$$\hat{\beta}^t = \frac{1}{SSx_t}\sum_i x^m_{t,i}\Pi^i_{t+1}, \tag{19}$$

where $SSx_t = \sum_i (x^m_{t,i})^2$ for each t. Once again, one can see that the average return on the signal-weighted portfolio is proportional to the regression coefficient from a Fama-MacBeth regression, upto a time-varying scalar, $\frac{k_t}{SSx_t}$. In another word, a time-weighted average return on a signal-weighted portfolio is equivalent to a panel regression, which is also equivalent to a Fama-MacBeth regression for some time-varying weighting scheme.

3 Data

For my empirical analysis, I collect data from Global Financial Data (GFD). GFD specializes in collecting long-term historical data from publications, such as newspapers, periodicals, and books across every country. Whereas most other research in this literature obtains data from Datastream, which provides forward exchange data at higher frequencies and with bid-ask spreads, GFD has the advantage of offering a longer historical coverage of data over a broader cross-section of currencies. Lustig and Verdelhan (2007), Ang and Chen (2017), and Lustig, Stathopoulos, and Verdelhan (2019) are examples of works in the literature that have also used the GFD data to analyze currency returns.

I obtain two sets of historical interest rate data: short-term interest rates (short rates) and the interest rate on longer maturity bonds (long bonds). Each of these

[10] This can further be shown to be equivalent to running a panel regression on non-demeaned signal $x_{t,i}$ with time-fixed effects.

series is obtained at the monthly frequency from GFD for as much history as possible. For the short rate, I first seek out the '3-month Treasury Bill Yield' for each currency in GFD, which goes back to the mid-20th century for most currencies, and as far back as 1900 for the British Pound (GBP). I then seek out the central bank discount rate to complete the data, which is available for a much longer history. For the GBP, this series begins in 1694, when the Bank of England was established. I start the dataset as of 1854:01, when interest rates for at least six currencies become available to ensure a broad enough cross-section. For the long bond, I seek out the '10-year Government Bond Yields' in GFD. In some cases, the yield is that of a shorter-maturity bonds, while it the yield of a perpetuity in other cases. In instances where a country did not historically exist, its primary predecessor is used, such as the Kingdom of Prussia for Germany.[11]

For historical foreign exchange rates, I obtain values of one US dollar for each currency from GFD across time. The data provider has made adjustments for foreign exchange conversions, such as the conversion of 100 old French francs for 1 new French franc, much in the same way stock prices are adjusted for stock splits. When foreign exchange rate versus the US dollar is unavailable, when possible, it is inferred from GBP foreign exchange rate or the Dutch guilder (NLG) foreign exchange rate, assuming no currency triangular arbitrage.[12] For currencies that entered the Euro, the data series end on 1998:12, with the exception of German Deutschemark (DEM), which I splice in with the Euro. All other data series end on 2017:06.

I focus on one-year holding period returns, so twelve months of foreign exchange

[11] In the earliest periods, such as the 18th century, data provided is the yield on the most comparable instrument, such as the dividend yield on a highly secure bank stock such as the Million Bank for England or the East India Company for India.

[12] Some additional missing data on the foreign exchange rate is inferred from the Swedish krona (SEK) foreign exchange rate available from the Riksbank (Lobell, 2010).

returns and interest rates must be available for a currency to be in my sample. To eliminate potential outliers due to periods of hyperinflation, I remove from the sample currencies that experience an absolute one-year foreign exchange return of more than 80%. Hence, my samples retain the initial period of hyperinflation when a currency depreciates five-folds but excludes subsequent periods.[13] This screen reduces the impact of hyperinflationary periods with minimal look-ahead bias but does not remove it altogether.

3.1 Descriptive statistics

I create two data samples, the first using short rates and the second using long bonds, and focus on one-year holding period returns. For currencies that entered the Euro with the exception of DEM, the sample ends on 1997:12, with a one-year return ending on 1998:12. For all other currencies, the sample ends on 2016:06, with a one-year return ending on 2017:06. Figure 1 shows the number of currencies represented in my samples across time. The short rate sample begins with 6 currencies represented in 1855:01, but steadily rises to include 21 currencies by the late the 1920s. The long bond sample begins with 8 currencies represented in 1788:09 and expands, with occasional drops, to include 21 currencies by the 1890s. This sample remains at 21 currencies with occasionally drops, notably during the period following World War II. Both samples fall to 13 currencies when the Euro is introduced, and the legacy currencies are removed.

Table 1 presents descriptive statistics of interest rate data in my sample. For each currency, I report means and volatilities in annual percentage terms, as well as

[13] As an example, the hyperinflationary period of the German Weimar Republic is generally agreed to have lasted from August 1922 to December 1923. My screen removes DEM from the sample only from July 1923 and retains the earliest part of the hyperinflationary period. DEM reenters the sample in December 1924 with the one-year return ending on December 1925.

the first month of observations. For the majority of currencies, I can obtain longer historical data by using the long bonds, rather than using only the short rates. The two exceptions are the Finnish markka (FIM) and the Swiss franc (CHF).

In almost every country, the average long-term interest rate has been higher than the average short-term interest rate, and the typical yield curve has been upward-sloping throughout history. The one exception has been in India, where the yield curve has been relatively flat on average. On the other end of the spectrum, Spain has historically exhibited the highest long-term bond rate. Much of this can be attributed to the high yield on bonds issued by the Spanish crown during the early 19th century when the Spanish government defaulted on its debt payments. This period also accounts for the high variability of long-term bond yields in Spain. Fortunately, the Spanish experience is more the exception rather than the rule. In other countries, long-term bond yields were much less variable and often less variable than the short-term interest rate.

4 Carry Trade Over the Recent Centuries

I now investigate the historical returns on investments made in foreign currencies and bonds over the recent centuries. I begin by summarizing individual currency investment returns and then analyze the carry trade. I later turn to foreign currency investment returns made using other signals.

4.1 Individual Currency Investment Returns

For each currency, I begin by computing total currency investment returns according to Equation (2), where investment return R^i_{t+1} is either the short rate or the long bonds held over twelve-months periods, as estimated by Equation (13). I use twelve months holding period as the base case specification, but use shorter holding periods as a robustness check. Table 2 shows the summary statistics of net investment returns, $R^i_{t+1} - 1$, net foreign exchange rate returns, $\frac{S^i_{t+1}}{S^i_t} - 1$, and net total returns, $R^{Tot,i}_{t+1} - 1$. When long bonds are used, the table also reports the capital gains component, with the estimation adjustment term η_t included. Columns labeled 'Short Rate Sample' use the short rate as the investment vehicle, while the columns labeled 'Long Bond Sample' use the long bonds as the investment vehicle.

In my data, short rates have been relatively stable compared to other variables, as shown by their low volatilities (standard deviations). The Swiss franc (CHF) has had one of the most stable short rates (volatility of 1.88%) and has also had the lowest average short rates (average of 2.82%). On the other hand, the Portuguese escudo (PTE) has had the most volatile short rates (volatility of 5.39%), as well as one of the highest average short rates (average of 6.26%). Generally speaking, lower average short rates have been associated with more stable short rates, with a correlation between them of 0.66.

On the other hand, foreign exchange returns have been historically more volatile and accounted for the bulk of the volatility of total returns when short rates are used as the investment vehicle. From the point of view of the US dollar, the most volatile investment currency has been the German mark (DEM), while by construction, the least volatile investment currency has been the US dollar (USD), followed by the Canadian dollar (CAD), the Swedish kroner (SEK) and the Indian rupee (INR). The Swiss franc (CHF) appreciated the most in this sample, followed by Dutch guilder (NLG) and then the US dollar (USD) while the Austrian shilling (ATS) and the Portuguese escudo (PTE) depreciated the most. Interestingly, currencies with the highest volatility relative to the US dollar have depreciated the most, with a correlation of -0.61 between average volatility and average currency appreciation. Taken together, although the high-yielding New Zealand dollar (NZD) produced the overall highest total investment returns, this has been the exception rather than the rule. Hassan and Mano (2019) decompose the carry trade into two components, a 'static trade' and a 'dynamic trade', and find that the static carry trade accounts for the bulk of the carry trade. In this initial overview, however, there is no indication of a static carry trade where countries with the highest overall yield across time produce the highest total investment return. The correlation between average total return and the short rate is only 0.05.

When I use the long bonds as the investment vehicle, patterns similar to that with the short rates emerge, except that investment returns are much more volatile due to the capital gains component. Investment returns from long bonds are still more stable than currency returns, with some notable exceptions. In particular, returns on Spanish bonds have been extremely volatile, particularly during the early 19th century. This volatility was also accompanied by very high returns on Spanish bonds, which was subject to default risk at the time. Even with the Spanish bonds removed, more volatile bonds have exhibited higher average returns with a correlation of 0.65 between average return and volatility. Much of this pattern is attributable to the bond yield components since average capital gains are generally close to zero. Overall, capital gains add volatility to investment returns but do not seems to contribute significantly to overall investment returns.

Patterns among currency returns remain similar with the highest volatility currencies producing the greatest currency depreciation, with a correlation between average volatility and an average appreciation of -0.45. While the Spanish bonds provided the highest carry and the highest total investment returns, if I exclude them, there is still no indication of a static carry trade and the correlation between average total investment return and the long-term bond rate is only -0.02.

4.2 Carry Trade Over the Modern Sample

With these currency investment returns in hand, I first confirm the integrity of my data by reproducing the well-known carry trade in the literature before examining the extended historical sample. The literature has primarily focused on the floating exchange rate period since 1973, which I refer to as the 'Modern Sample'. I follow the portfolio formation process described in Section 2.4 and begin with monthly-rebalanced equal-weighted long-short portfolios using the short-rate as the investment vehicle. Monthly-rebalanced equal-weighted portfolio is the most often used specification in the literature. I vary the portfolio formation process to ensure that these results are robust to specification of the portfolio formation process.

Panel A of Table 3 shows the characteristics of these monthly-rebalanced equal-weighted portfolio returns. Columns labeled 'Short Rate Portfolios' use the short-term interest rates as the investment vehicle. Long-short portfolios using the short rate has produced an average return of 3.42% per year with a volatility of 6.45% during this modern period. This is a Sharpe ratio of 0.530, which is comparable to that of earlier research.[14] Since there are 44.5 years of returns, this Sharpe ratio is equivalent to a t-statistic of 3.54 using ordinary standard errors. In this sample, there is only a little evidence of negative skewness with a coefficient of skewness of 0.64 and a minimum one-month return of -9.93% return, indicating that crash risk is not a significant factor in this sample. The long-short portfolio return is decomposed into the long-side and the short-side by comparing each side to returns on equal-weighted portfolios that invest evenly across all currencies.[15] The decomposition

[14] Some research report higher Sharpe ratios using a wider cross-section of currencies (Lustig, Roussanov and Verdelhan, 2011) or specifying a currency portfolio that is not neutral with respect to all currencies (Burnside, Eichenbaum, Kleshchelski and Rebelo, 2011). Later, I explicitly examine the robustness of dollar carry trade presented by Lustig, Roussanov and Verdelhan (2014).

[15] Some articles in the literature report excess return relative to USD risk-free rate, which is not

is presented under the columns labeled 'Long Side' and 'Short Side' and show that each side has similar characteristics during the Modern Sample. If anything, it is the long-side currency investment that has contributed slightly greater return, with a comparable level of volatility. Interestingly, the Sharpe ratios are not significantly different across the long side and short side.

I first vary the investment vehicle to long-term bonds in columns labeled 'Long Bond Portfolios' in Panel A to see if using an alternative investment vehicle affects the carry trade during the Modern Sample. During this period, long-short portfolios using the long bonds has produced an average return of 2.52% per year with a volatility of 6.43% for a Sharpe ratio of 0.392. Interestingly, even though individual long bonds are riskier with greater volatility due to exposures to capital gains, portfolios of currency investments with long-term bonds are not any riskier than portfolios of currency investments using short rates. However, the average return and consequent Sharpe ratio of 0.392 are somewhat lower using long bonds than with short rates. But they are still economically significant and statistically significant with a t-statistic of 2.61. This result is in contrast to Lustig, Stathopoulos, and Verdelhan (2019), who report insignificant carry trade returns using long bonds over the Modern Sample. However, my estimation of long bond returns differ from theirs in a number of ways, which may explain the differences.[16]

Panel B of Table 3 illustrates the portfolio characteristics when carry trade portfolios are annually-rebalanced at the end of each December, instead of monthly rebalancing. Since historical data is more reliable at the annual frequency and transaction

currency-neutral. Other articles report absolute portfolio returns, which is difficult to interpret because it is not feasible to obtain zero returns.

[16] Specifically, I directly infer long bond returns from observed yields, rather than rely on estimates provided by GFD. Moreover, my predictive variable is the yield on long bonds, rather than short rates.

costs associated with excessively frequent rebalancing is a potential concern, I use annually-rebalanced portfolios as the main specification in the extended historical sample. Most research on carry trade that use the forward rate focus on one-month forwards and incorporate bid-ask spread on a new forward contract on a monthly basis. Nevertheless, I begin by checking that the well-researched carry trade is not affected by less frequent rebalancing. Indeed, qualitative results do not materially change with annual-rebalancing, but is subject to less transaction cost concerns. With equally-weighted portfolios, annually-rebalanced portfolios are generally riskier with slightly lower returns. Sharpe ratios are 0.373 and 0.356, using short rates and long bonds, respectively, which remain economically and statistically significant. It remains the case that the long side of the carry trade portfolios contributes just as much, if not greater proportion of returns, than the short-side of the carry trade portfolios. Moreover, it remains the case that there is not significant evidence of negative skewness or extreme negative returns, whether the short rates or the long bonds are used.

Finally, I consider signal-weighted carry trade portfolio returns in Panel C of Table 3. Unlike equal-weighted portfolios, signal-weighted portfolios place greater portfolio weight on more extreme yields, akin to regression analysis. The resulting portfolio is qualitatively similar to equal-weighted portfolios presented in Panel B, with some notable features. Overall returns are slightly higher, but they have higher volatility, which results in Sharpe ratios of 0.391 and 0.361, depending on whether short rates or long bonds are used as the investment vehicle. Long-short portfolios exhibit slightly less negative skewness, of which much of the change seems to be coming from the long-side portfolio rather than the short-side portfolio.

Table 4 provides some indications of how similar these portfolios are by presenting the correlations among portfolio returns over the Modern Sample. Not too surprisingly, annually-rebalanced equal-weighted and annually-rebalanced signal-weighted portfolios are strongly correlated with correlations of 0.954 and 0.929 for short rate portfolios and long bond portfolios, respectively. On the other hand, currency portfolios using short rates are slightly distinct from currency portfolios using long bonds. The correlation of returns between equal-weighted short rate currency investment portfolio and that of the long bond portfolio is 0.884, which further drops with annual rebalancing to 0.857 and 0.838 for equal-weighted portfolios and signal-weighted portfolios.

Overall, these tables show that my dataset created from GFD replicates empirical results consistent with that found in the existing literature. Moreover, the qualitative results of the carry trade are not affected by various specification changes. Namely, the carry trade is robust to using short rate or long bonds as the investment vehicle and is not limited to using forward rates. Furthermore, the carry trade can be constructed using annually-rebalanced portfolios, which mitigates transaction cost concerns. Finally, the carry trade can be signal-weighted rather than equal-weighted. With these concerns out of the way, I now examine extended historical samples spanning a mmuch longer time.

4.3 Historical Carry Trade Returns

I use the period from 1855 to 2017 as the 'Main Sample', and for long bonds, use an extended period starting in 1789 as the 'Extended Sample'. In this extended sample, I focus on annually rebalanced equally-weighted long-short portfolios of using both the short rate and the long bond as the investment vehicle. In the robustness section, I also consider using annually rebalanced signal-weighted portfolios and monthly panel regressions.

I begin by plotting cumulative returns across the entire sample in Figure 2. The cumulative returns are normalized to equal one hundred USD at the end of

1854. This plot shows some preliminary indication that while there are some time-variations in the characteristics of currency investment portfolio returns, the carry trade would have been surprisingly robust. For instance, before 1854, portfolios were significantly more volatile, but the returns were noticeably higher on average. The portfolio returns were extremely stable during the following period until the start of the World Wars and became significantly volatile during the wars. There is one particularly notable period immediately following World War II and the introduction of the fixed exchange rate regime under the Bretton Woods Agreement during the post-war reconstruction efforts. Doskov and Swinkels (2015) note this period as an influential observation, while Accominotti, Cen, Chambers, and Marsh (2019) attribute the low carry trade return to the change from floating exchange regime to fixed exchange regime. During the post-war period, portfolio returns were once again reasonably stable. Most notably, currency investment portfolio returns remained positive throughout the entire sample.

I investigate the sources of carry trade portfolio returns in detail by decomposing portfolio returns across time and into components of returns. I divide the sample into seven major time periods of roughly 22 years each: Early Second Industrial Revolution (1855-1879), Classic Gold Standard Era (1880-1913), World War Era (1914-1949), Bretton Woods Era (1950-1972)[17] , Pre-Euro Floating Exchange Regime (1973-1998), and Post-Euro Floating Exchange Regime (1998-2017). I also decompose portfolio returns into a component that is attributable to foreign exchange returns ('FX Returns') and the remainder attributable to the yield on the short rate ('Carry Returns'). For each return component, I also report its standard deviation ('Vol').

[17] Bretton Woods Agreement was introduced in 1946, but there were still significant adjustments to fixed exchange rate pegs of European currencies until September of 1949. Hence I use 1950 as the beginning of the Bretton Woods Era.

Table 5 presents the results of this exercise for annually rebalanced equal-weighted currency investment portfolios based on short rates. As already indicated in Figure 2, Table 5 also shows that currency investment portfolio returns were positive during each of the subsamples, except at the end of the World War Era. However, there were significant time-variations across these periods, particularly in the volatility of the portfolios. The Classic Gold Standard Era, when currencies were primarily pegged to the value of gold, produced one of the lowest volatility of returns. As a result, this period resulted in the highest carry trade portfolio with a Sharpe ratio of 1.200. The World War Era was accompanied by the greatest volatility and the lowest Sharpe ratio. This period was followed by the fixed-exchanged rate regime of the Bretton Woods Era that produced one of the lowest returns, but like the Classic Gold Standard Era, the volatility of currency investment portfolios was very low and contributed to a very high Sharpe ratio of 0.714. The oft studied Floating Exchange Regime produced high carry trade returns, particularly in the period after the Euro was introduced. The overall picture is that equal-weighted currency investment portfolios based on short rates produced consistently positive returns across different periods, with a single exception, but significantly differed in its volatility depending on the exchange-rate regime and the stability of the global economy.

Most notably, the average FX returns has been generally been negative and much of the currency investment returns would have come from capturing the yield component of returns ('carry returns'). On the other hand, much of the risk associated with currency investment would have come from FX returns rather than from the yield component. These characteristics are consistent throughout the subsamples. Overall, much of the positive returns associated with currency investing would have come from capturing the yield differential among short rates, while accepting the risk of currency fluctuations. Whereas the Uncovered Interest Rate Parity Hypothesis would have predicted that such interest rate differentials would have led to adverse changes in currencies, such changes did not ever materialize during the recent centuries.

Table 6 presents the results for the equal-weighted currency investment portfolios based on long bonds. Since I can obtain a longer sample for long bonds, this table adds the eighth period at the beginning: Age of Revolutions (1789-1854). With long bonds, I can further decompose currency investment returns into a third component attributable to capital gains on holding long-term bonds, ('Cap Gains'). As with the short-rates, I observe similar patterns across time. Overall, carry trade portfolio returns were consistently positive across periods when long bonds are used as the investment vehicle. However, the riskiness of the portfolio varied depending on the exchange-rate regime and the stability of the global economy. As before, the World War Era was associated with one of the most volatile periods for currency portfolios, only to be surpassed by the volatility of the Age of Revolutions. The least volatile period is still the Bretton Woods Era, which led to the period with the highest Sharpe ratio for the carry trade with long bonds.

Similar to the case with short-rates, investing in high yield bonds was not met with depreciation in currencies, and it was also not met with capital losses in the values of long bonds. If anything, the capital gains component of returns was positive and would have added further to currency investment portfolio returns. Furthermore, the capital gains component was volatile and added risk to the portfolio returns. During the Age of Revolutions, long term bonds were highly volatile, but became less volatile during the Early Second Industrial Revolution and much less so in the following periods. Overall, when long bonds are used, the strategy of capturing yield differential while accepting the risk of currency fluctuations and the risk of capital losses would have provided additional returns and positive Sharpe ratios.

4.4 Robustness of Carry Trade Returns Across Time

The previous section established that the carry trade, both in terms of using the short rate or the long bond, would have been reasonably profitable throughout the recent centuries, except for the period surrounding the economic turmoils associated with the World Wars and the recoveries from them. I now investigate the robustness of this result with respect to the specification of the analysis.

I begin by computing the returns on signal-weighted portfolios described earlier in Section 2.4 over the extended data sample. In addition, to allow for appropriate statistical inference, I run panel regressions of the form:

$$\Pi^i_{t+\Delta t} = \alpha_t + \sum_{\text{Era}} \beta_{\text{Era}} \mathbf{1}_{t\in\text{Era}} x_{t,i} + \epsilon_{t,i}, \tag{20}$$

where indicator functions, $\mathbf{1}_{t\in\text{Era}}$, equal 1 for observations in each time period. Unlike equal-weighted portfolios, both signal-weighted portfolios and panel regressions place greater weight on extreme observations that deviate more from the means. As discussed in Section 2.4, the average returns on signal-weighted portfolios, coefficient estimates of panel regressions with time fixed effects, and coefficient estimates of Fama-MacBeth regressions are all related to one another up to a time-varying scalar.[18]

Equation (20) is first estimated as panel regressions with time fixed-effects, which absorbs the effects of time-varying means. Hence in this specification, the results are driven by cross-sectional variations at each point in time.[19] The regression framework easily allows for the use of overlapping observations where holding period, Δt,

[18] Petersen (2009) offers detailed discussions of the differences between Fama-MacBeth regressions and panel regressions with clustered standard errors.

[19] Unlike the carry trade, tests of Uncovered Interest Rate Parity are driven by time-series variations between currency pairs. Hassan and Mano (2019) decompose this distinction in further detail.

might be longer than the frequency of observations of time, t. When running regressions, I consider 12-month holding periods as before but use all monthly observations rather than portfolios formed only in December. Using overlapping observations will mechanically understate standard errors because two subsequent observations are related to one another due to the overlap. Moreover, standard errors might also be overstated because some currency pairs are naturally related to one another and are not genuinely independent observations. In order to control for these two effects, the standard errors are computed using two-way clustering by time and by currencies following Petersen (2009) and Thompson (2011).[20] As a further robustness check of the specifications, I also run monthly Fama-MacBeth regressions. Since standard errors based on overlapping observations are still a concern with this method, I produce Newey-West standard errors following Newey and West (1987).[21]

Table 7 shows the robustness of the short rate carry trade to these specifications. Panel A shows the returns on signal-weighted short rate carry trade portfolios over recent centuries. Over the whole sample, the average return of 2.14% per year with a volatility of 9.52% is comparable to that of the equal-weighted short rate carry trade shown in Table 5. The Sharpe ratio is essentially unchanged at 0.225. Within each period, neither the average returns nor volatilities are substantially changed. It remains the case that the short rate carry trade was not profitable during the World War Era but experienced significantly reduced volatility during the Class Gold Standard Era and Bretton Woods Era. As a result, short rate carry trade was most profitable in terms of Sharpe ratios during these two periods when currencies were

[20] While the two-way clustering method is commonly used in empirical asset pricing, this method assumes that cross-autocorrelations are equal to zero. Hence, if there is a lead-lag effect across currencies, the standard errors would still be overstated.

[21] To further alleviate concerns associated with overlapping observations, I also ran annual non-overlapping regressions using observations only in December, and the results were not materially different.

not freely floating, regardless of using equal-weighted portfolios or signal-weighted portfolios.

Examining regression results allows for making more careful statistical inference than casually looking at average returns and Sharpe ratios. The estimates of panel regressions with time fixed-effects and clustered standard errors are denoted $\hat{\beta}^{\text{Panel}}$ and shown in Panel B of Table 7. The total number of observations is 33,321 across time and across currencies. The column labeled 'Whole Sample' shows the regression result of Equation (20) without changing the indicator function across periods. A coefficient estimate of 0.367 indicates that when short rate of a currency is higher by 1% relative to that of other currencies, on average, the total investment return in the short rate of that currency was greater by 0.367%. Put another way, given an increased short rate carry of 1% return, an average of 0.367% return was not lost to currency depreciation. This estimate is statistically significant at the 1% level, even after controlling for both clustering by time and by currency.

The remaining columns of Panel B show the coefficient estimate with indicator functions for each period. These estimates can be interpreted as time-varying effects of the short rate carry trade. Consistent with the portfolio results, the panel regression estimates show that there was no short rate carry effect during the World War Era. Curiously, despite the modest Sharpe ratio of 0.389 shown in Panel A over the Early Second Industrial Revolution, the panel regression estimate for this period is not statistically significant. Part of this can be explained by the fact that the short rate carry trade is less pronounced when overlapping data is used during this period, but it is also due to the more conservative inference made with two-way clustered standard errors.

As an additional specification check, the estimates from Fama-MacBeth regressions are denoted $\hat{\beta}^{\text{FM}}$ and shown in Panel C. Across the whole sample, the coefficient estimate is 0.308 and remains statistically significant using Newey-West standard errors. The remaining columns of Panel C show the coefficients estimates from Fama-MacBeth regressions over each period and are equivalent to the estimates from the panel regressions with indicator functions. Consistent with panel regression results, Fama-MacBeth regressions also fail to detect statistically significant short rate carry trade returns during the Early Second Industrial Revolution and the World War Era.

Table 8 repeats the robustness checks to varying specifications for the carry trade using the long bonds. Panel A shows the returns on signal-weighted long bond carry trade portfolios, which are similar in terms of Sharpe ratios to that of equal-weighted long bond carry trade portfolios shown in Table 6. However, both average returns and volatilities are significantly higher in the extended sample that covers the Age of Revolutions. Similar to the short rate carry trade, the long bond carry trade was also not profitable during the World War Era. The lack of long bond carry trade during this time period is confirmed by the panel regression results in Panel B and Fama-MacBeth regression results in Panel C. With the long bond sample the total number of observations increase to 45,122 across time and across currencies. However, unlike the short rate carry trade, the regression results support a statistically significant long bond carry trade during the Age of Revolutions and the Early Second Industrial Revolution. The regression point estimates are larger for long bond carry trade, but harder to interpret, that those for the short rate carry trade. The point estimate from the panel regression of 1.851 for the whole sample in Panel B indicates that given an increased long-term bond yield of 1% is associated with more than one-for-one total investment return, some of which is due to carry and lack of currency depreciation, but also due to capital gains as future yields fall. Compared to the short rate carry trade, the regression point estimates are generally higher for the long bond carry trade across periods, but converges during the Modern Sample.

Overall, my extension of the study of the carry trade indicates that the carry trade is robust to using the long bonds and extending the sample to longer time, but with some exceptions. In particular, neither the short rate carry trade nor the long bond carry trade appears to have produced positive returns during the World War Era. While Accominotti, Cen, Chambers, and Marsh (2019) argue that it was the transition to fixed exchange rate that leads to reduced carry trade returns, such an argument doesn't explain the robust carry trade returns around the Classic Gold Standard Era or the lack of change in returns when exchange rates become floating once again. If anything, fixed exchange rate eras, such as the Classic Gold Standard Era or the Bretton Woods Era, led to reduced volatility of exchange rates and ultimately made both the short rate carry trade and the long bond carry trade more attractive in terms of Sharpe ratios. Various specification tests of this also show that the carry trade is robust to focusing on just the long side or the short, using signal-weighted portfolios, using overlapping data in a regression analysis, and using clustered standard errors.

5 Other Currency Investment Portfolios

With these extended data samples of the short rate and long bonds over the recent centuries, I can also investigate the robustness of other currency investment strategies based on additional signals studied in the literature. I begin by examining a version of the carry trade that places the US dollar in a central position, called the dollar carry trade. Then I examine the robustness of the momentum effect and the reversal effect among currencies. Finally, I examine the robustness of a currency investment strategy that uses the slope of the yield curve as the signal.

5.1 Dollar Carry Trade

Lustig, Roussanov, and Verdelhan (2014) and Hassan and Mano (2019) examine a variation of the carry trade that focuses explicitly on the level of the USD short rate relative to that of the average of all other currency's short rates. This strategy goes long all other currencies and goes short USD whenever the average global short rates are above the US short rate. Similarly, the strategy goes long USD whenever the US short rate is high relative to that of other currencies. Lustig, Roussanov, and Verdelhan (2014) show that this strategy delivered substantial returns from 1983 to 2010, even after controlling for transaction costs by using forward contracts. They argue that the relative level of the US short rate is related to the US economic cycle, and interpret the high excess return on this portfolio strategy as a risk premia in currency markets for macroeconomic risk. Hassan and Mano (2019) reexamine the potentially unique role of the US dollar in a regression framework and find some support.

Using the same methodology I used for the normal carry trade, I examine the robustness of the dollar carry trade to earlier historical samples. One problem with this exercise is that the short rate for the US can only be obtained going back to 1914:11 in my data source.[22] Fortunately, using long bonds allows historical data to reach as far back as 1788:09. When using long bonds, dollar carry trade portfolios are constructed using the yield on the long-term US bond rate relative to the average of all other currency's long-term bond rates. With both investment assets, I focus on annually-rebalanced equal-weighted portfolios. Results based on monthly rebalancing or signal-weighting are similar but not shown. For robustness,

[22] The 3-month US Treasury bill rate is available on (FRED) from 1934. Before this, other short-term US Treasury securities and the discount rate of the Federal Reserve Bank of New York is used.

I also present results based on overlapping monthly panel regressions.

Table 9 shows the returns on dollar carry trade over the extended time sample. Panel A presents the dollar carry trade using the short rate going back to 1914. Consistent with the literature, the dollar carry trade produced positive returns during the Modern Sample, albeit with only moderate Sharpe ratios. During the fixed-exchange regime of Bretton Woods Era, the return on the dollar carry trade was modest at only 0.89% per year, but this was a period of very low volatility in currency exchanges. Overall, the Bretton Woods Era would have produced the dollar carry trade with the highest Sharpe ratio. However, as with the normal carry trade, the World War Era remains the exception. During this period, the dollar carry trade would not have been positive. If anything, the dollar carry trade would have been negative. Hence, it may have be the case that the dollar carry trade doesn't hold up to the robustness test of using an extended sample. Alternatively, it may also have been the case that the underlying economic mechanisms at work was different during the period surrounding the World Wars and the recovery periods.

Panel B of Table 9 shows results using long bonds in place of short rates. The long bond sample shows weak returns on the dollar carry trade in the most recent half of the Modern Sample in the Post-Euro Floating Exchange Regime. As with the normal carry trade, returns would have been smaller during the Bretton Woods Era and the Classic Gold Standard Era, but the reduced currency volatility of the period would have made the Sharpe ratios of the dollar carry trade attractive. In fact, the long bond dollar carry trade would have been positive in all other periods except during the World War Era and the Early Second Industrial Revolution. Figure 3 plots the cumulative returns on both the dollar carry trade using the short rate and the long bond and provides a clear view on when the dollar carry trade failed to produce positive returns. The points in time when the dollar carry trade produced significantly negative returns correspond to the US Civil War period and the recovery periods after the two World Wars. Hence rather than economic cycles, the performance of dollar carry trade might be more tied to periods of extreme economic turmoils.

As a final robustness check, I run monthly overlapping panel regressions with two-way clustered standard errors. In the case of the dollar carry trade, the independent variable, $x_{t,\text{USD}}$, equal one (negative one) if the US dollar interest rate is greater (lower) than the average interest rate of all other currencies. For all other currency i, $x_{t,i}$ equals positive (negative) $1\%/(n_t - 1)$ if the US dollar interest rate is lower (greater) than the average interest rate of all other currencies, where n_t is the number of currencies in the sample at time t. As with before, this variable is interacted with an indicator function for each period.

Panel C of Table 9 presents the results from the panel regressions for the short rate dollar carry trade and for the long bond dollar carry trade. Results using Fama-MacBeth regressions with Newey-West standard errors are not shown but are similar. Since the US dollar short rate is not always available, the total number of observations for the short rate sample fall to 23,291 across time and across currencies. The coefficient estimate of 0.609 for the short rate dollar carry over the whole sample can be interpreted as when the US dollar interest rate is above average, investing in the US dollar produced an average of 0.609% return per year. The coefficients with the period interaction terms show time variation in the short rate dollar carry trade. Consistent with the portfolio results, the panel regression using short rates shows that dollar carry trade produced positive returns during the Modern Sample and extended back to the Bretton Woods Era, but not back to the World War Era. The coefficients on the long bond dollar carry trade show qualitatively similar results, but with a higher overall impact. As before, dollar carry trade produced negative returns around the Early Second Industrial Revolution, which contained the US Civil War period and the recovery period after the two World Wars. Overall, these results suggest that the dollar carry trade is fairly robust except during periods of extraordinary economic turmoil, which is similar to the lack of robustness of the normal carry trade during such times. This lack of robustness might help explain the mechanism underlying both carry trades.

5.2 Currency Momentum and Reversal (Value)

The momentum effect and the reversal (value) effect are two additional currency investment strategies that have been studied in the literature. Menkhoff, Sarno, Schmeling, and Schrimpf (2012a) and Asness, Moskowitz, and Pedersen (2013) both report strong momentum effect in the Modern Sample during which currencies that have appreciated the most in the past twelve months tend to continue to have high returns. Menkhoff, Sarno, Schmeling, and Schrimpf (2012a) report that this effect is most potent when the holding period is over the next one month, which is consistent with the strategy studied in Asness, Moskowitz, and Pedersen (2013). The latter study also documents a reversal effect, where currencies with low long-term past returns tend to revert to higher returns. Menkhoff, Sarno, Schmeling, and Schrimpf (2017) report similar results based on past 5-year currency appreciation, relative to changes in purchasing power.[23] Since low past returns given relatively unchanged fundamentals are similar to low valuation of currencies, these reversal effects are sometimes referred to as 'value' effects. These studies are all based upon observations during the Modern Sample. In this section, I investigate the robustness of momentum and reversal effects in currencies over extended periods.

In studying the momentum effect, I follow Menkhoff, Sarno, Schmeling, and Schrimpf (2012a) and focus on a one-month holding period, which they found to

[23] There is also a vast literature examining the Purchasing Power Parity (PPP) throughout history, but that literature focuses on time-series variation in currency pairs rather than cross-sectional variations across multiple currencies at a point in time.

exhibit the strongest momentum effect, by considering monthly-rebalanced portfolios and monthly overlapping panel regressions. I use past twelve month FX returns, excluding the carry, as the sorting variable, which Menkhoff et als. (2012a) found to be stronger than using past total investment returns.[24] Figure 4 shows the cumulative returns on currency momentum based on using both the short rate and the long bond as the investment vehicle. This figure indicates a generally positive return to momentum investing in currencies since 1855 when the short rate sample begins. Unlike the carry trade, currency momentum would have remained robust during the World War Era. However, when we extend the data sample back to the Age of Revolutions using long bonds, the resulting plot casts doubt on the robustness of currency momentum strategy throughout the entire sample.

Panel A of Table 10 examines the robustness of the monthly-rebalanced equal-weighted momentum strategy across time. While the currency momentum effect has existed in the Modern Sample, it appears that the effect has been negligible during the most recent Post-Euro Floating Exchange Regime. However, in all other periods, currency momentum has exhibited positive Sharpe ratios. Even during the Bretton Woods Era and the Classic Gold Standard Era, when overall momentum return was low, coupled with low volatility of this era meant that momentum offered reasonable returns for the amount of risk taken. Curiously, the World War Era was the period that produced the highest momentum returns in terms of Sharpe ratios. Panel B of Table 10 re-examines the momentum effect using the long bond as the investment asset instead. The results are largely consistent with that of currency momentum using the short rate. Consistent with Figure 4, Panel B reflects the fact that the

[24] An alternative method would be to create a strategy based on past total investment returns that include both past carry and past capital gains of the investment asset. However, this would confound the results from the carry trade and from any momentum and reversal effects of long-term bonds.

momentum effect was negative during the Age of Revolutions.

Panel C of Table 10 shows the results based on monthly panel regressions with two-way clustered errors. The combined regression results suggest that short rate currency momentum may not be very robust. Based on the short rate as the investment vehicle, currency momentum effect over the whole sample is only statistically significant at the 10% level. In fact, the only period when the momentum effect was statistically significant was during the World War Era. Panel C also shows the results based on currency momentum investing in long bonds. The currency momentum investing can be shown to have been significant during the first half of the Modern Sample, but it is offset by the statistically significant negative effect during the Early Second Industrial Revolution. Over the whole sample, the long bond momentum effect can not be shown to have been statistically significant.

Next, I examine currency reversal trade over my extended data sample. Annually-rebalanced equal-weighted portfolios are formed according to the past five years of FX returns. Inflation is not used, and portfolios are formed using only past returns. This formation is equivalent to the currency reversal strategy studied by Asness, Moskowitz, and Pedersen (2013) rather than currency value strategy studied by Menkhoff, Sarno, Schmeling, and Schrimpf (2017) which uses real returns in foreign exchange. As before, I consider investments in both short rate and long bonds.

Figure 5 shows the cumulative returns on currency reversal. Both short rate currency reversal and long bond currency reversal have only been positive since around 1980, when most prior studies begin their data. There has been period of relatively flat returns when currencies were not freely floating, but the general trend in returns to currency reversal has been negative. Table 11 examines returns on currency reversal portfolios deeper. Panels A and B show the returns using short rates and long bonds, respectively, and tell results similar to that of the figure.

The only period during which currency reversal produced significantly positive returns was during the latter part of the Modern Sample. Returns were relatively flat during the Classic Gold Standard Era and the Bretton Woods Era. Similar to the carry trades, if anything, returns were negative during the World War Era. Monthly overlapping panel regressions in Panel C confirm these findings. Some periods such as the Early Second Industrial Revolution and the Classic Gold Standard Era, do manage to produce statistically significant coefficients on currency reversal, but the overall effect throughout the whole sample is not statistically different from zero. While it is possible that the results would differ under other specifications of currency value that accounts for inflation and changes in purchasing power, this evidence based on a long history of currency reversal does not bode well for robustness currency value strategies.

5.3 Currency Term Spread (Slope) Trade

Ang and Chen (2017) show that in addition to the level of interest rates, the slope of the yield curve, or the term spread, has predictive power over future currency investment returns. That study provides empirical evidence that a relatively flat yield curve in currency compared to other currencies predicts positive future currency returns. Ang and Chen (2017) offer an interpretation that the term spread reflects a latent risk factor. Since the extension of the data includes both short-term interest rates and long-term interest rates, it is natural to check the robustness of this result to the extended historical sample. Moreover, whereas Ang and Chen (2017) only considered using the short rate as the investment vehicle, I can now use long bonds as the investment vehicle instead.

Yield curve slope trades are based on the term spread, which is simply the long-term interest rate minus the short-term interest rate. When short rates are the investment vehicles, the currency term spread trade goes long currencies with the lowest term spread and short currencies with the steepest yield curve. However, when long bonds are the investment vehicles since no guidance predicts which direction to expect the trade to go, I consider going long currencies with the steepest yield curve. As before, I construct annually-rebalanced equally-weighted portfolios and run monthly overlapping panel regressions with two-way clustered standard errors for robustness tests.

Figure 6 shows cumulative returns on currency term spread trades throughout the whole sample. Both short rate and long bond portfolios generally exhibit positive returns throughout the sample. Even though they are individually increasing, because they are constructed using opposite signals, the two portfolios are naturally complementary and exhibit strongly negatively correlated returns. Indeed, negative returns exhibited by the long bond portfolio during the 1920s is accompanied by positive returns in the short rate portfolio. However, during the Classic Gold Standard Era and the Bretton Woods Era when currencies were fixed, the two portfolios seem to behave independently, and both produced positive returns. Panels A and B of Table 12 show detailed statistics of these two portfolios across different periods. Consistent with the plots, both portfolios exhibit positive returns across all sub-periods, except for the long bond currency term spread portfolio over the World War Era and Post-Euro Floating Exchange Regime. Consistent with other strategies studied, portfolio returns were less volatile during the fixed exchange regimes, which produce high Sharpe ratios during these periods.

The negative correlation between the short rate and the long bond currency term spread trades suggests using a third portfolio, which I refer to as 'long-short spread' portfolio. This portfolio goes long long bonds and goes short short rates when the term spread in a currency is steep relative to others. Similarly, the portfolio would go short long bonds and go long short rates when the term spread is relatively flat. This strategy is essentially a cross-currency yield-curve flattening trade. Lustig, Stathopoulos, and Verdelhan (2019) consider a similar portfolio, but only for the Modern Sample. Panel C of Table 12 shows the portfolio returns on this long-short spread currency term spread trade. This spread portfolio produces positive returns throughout all sub-periods. In some periods, this spread produces the highest Sharpe ratio of all strategies considered thus far.

As a robustness test, Panel D of Table 12 shows the coefficient estimates from panel regressions for currency term spread trade using short rates, long bonds, and long-short spread. Since both the short rate and the long bond must be available, the intersection of the short rate sample and the long bond sample leaves total number of 32,280 observations across time and across currencies. Once again, results using Fama-MacBeth regressions with Newey-West standard errors are not shown but are similar. Consistent with Ang and Chen (2017), the short rate currency term spread trade is significantly positive during the Modern Sample. Before the Modern Sample, coefficients are generally positive but not statistically significant. For the long bond currency term spread trade, the regression coefficients vary greatly from strongly positive during the Early Second Industrial Revolution and Bretton Woods Era, to negative during the Post-Euro period. The most interesting result is for the long-short spread currency term spread trade. The panel regression coefficient is consistently positive and statistically significant throughout all periods. The average coefficient across all periods is 1.204 (unreported), which can be interpreted as whenever the term spread of a currency is higher by 1%, investing in that currency's long bond by financing it with that currency's short rate yields a return on average of 1.204%. Part of this is due to the higher yield, but it is also partly due to the fact that flattening yield curves lead to capital gains in long bonds. Overall, long-short spread currency term spread trade is surprisingly robust and profitable throughout the sample.

6 Conclusion

I investigate in this paper the robustness of currency investment strategies using an extended data sample that spans over two centuries and uses long-term bonds as well as short-term rates as the investment vehicle. Using portfolio returns and panel regression analysis, I find that the carry trade returns would have been robust across time, whether short rates or long bonds are used, except for the period surrounding the World Wars. The dollar carry trade also has been robust except for these periods plus the period surrounding the US Civil War. While there is some support for the currency momentum effect, using a longer sample shows that currency reversal effect does not exist. Finally, an examination of currency investments based on slopes of the yield curve suggests that cross-currency yield-curve flattening trades are surprisingly robust throughout the years.

Some surprising stylized facts seem to emerge from this study. Fixed exchange rate regimes do not seem to make currency effects like the carry trade go away. Since these periods exhibit reduced currency exchange rate volatility, if anything, these periods are associated with higher returns on a risk-adjusted basis. Rather than economic cycles, it seems to be the case that it is the periods of major economic turmoil associated with world wars that make these currency effects go away.

While this paper offers some initial understandings of the patterns of the cross-section of currency returns over the recent centuries, this line of research is still far from complete. In particular, this study investigated cross-country variations in currencies and did not investigate cross-time variations in currency investment returns, as is done in studies of PPP and UIP hypothesis. Moreover, I leave for future research the study of understanding the underlying economic mechanism behind these observations. It could be the case that some effects appear in a sub-period as the result of statistical error. Alternatively, it could also be the case that the underlying economic mechanisms are continually changing across periods and risk premia are observed in some periods and not in others.

This table reports means and standard deviations of interest rate data used. Short rates are the yields on three-month government bill rates or the closest available instrument. Long bonds are the 10-year government bonds or the closest available instrument. ISO 4217 code is used for currency code. The start of the sample is also reported. For currencies that entered the Euro with the exception of DEM, the sample ends with 1998:12. For all other currencies, the sample ends with 2017:06.

This table shows the summary statistics of 12-months investment returns. Columns under 'Short Rate Sample' and 'Long Bond Sample' report summary statistics for when short rates and long bonds are used, respectively. Columns labeled 'Yield' show means and standard deviations of twelve-months yield on short rates and long bonds. Returns on short rate are 3-months interest rates compounded for 12-months. Returns on long bonds are approximated as per Section 2.2 and include capital gains and adjustment term in the column labeled 'Cap Gains'. Columns labeled 'FX Return' show means and standard deviations of twelve-months returns on foreign exchange over the sample period. Columns labeled 'Total Return' show the averages the products of investment returns and foreign exchange returns. All values are in annual percentages.

Table 3: Carry Trade: Modern Sample (1973-2017)

	Short Rate Portfolios			Long Bond Portfolios		
	Long-Short	Long Side	Short Side	Long-Short	Long Side	Short Side
Panel A: Monthly-Rebalanced Equal-Weighted Portfolio Returns						
Average Return	3.42%	1.92%	1.50%	2.52%	1.34%	1.18%
Volatility	6.45%	3.55%	3.50%	6.43%	3.81%	3.16%
Sharpe Ratio	0.530	0.541	0.428	0.392	0.350	0.374
Skewness	(0.64)	(0.30)	(0.80)	(0.43)	(0.35)	(0.39)
Minimum	-9.93%	-3.86%	-6.33%	-7.28%	-3.90%	-3.67%
Maximum	5.86%	4.16%	3.53%	5.71%	4.05%	3.27%
Panel B: Annually-Rebalanced Equal-Weighted Portfolio Returns						
Average Return	3.04%	1.76%	1.28%	3.28%	1.77%	1.52%
Volatility	8.14%	3.94%	4.81%	9.21%	5.21%	4.70%
Sharpe Ratio	0.373	0.446	0.266	0.356	0.339	0.323
Skewness	(0.55)	0.06	(0.82)	(0.47)	(0.44)	(0.54)
Minimum	-24.30%	-8.14%	-16.16%	-20.86%	-11.19%	-12.79%
Maximum	23.93%	12.56%	11.36%	20.32%	12.68%	12.09%
Panel C: Annually-Rebalanced Signal-Weighted Portfolio Returns						
Average Returns	3.51%	2.21%	1.30%	4.26%	2.79%	1.47%
Volatility	8.99%	5.67%	4.15%	11.81%	8.67%	4.54%
Sharpe Ratio	0.391	0.390	0.313	0.361	0.322	0.325
Skewness	(0.16)	0.44	(1.20)	(0.20)	(0.13)	(0.40)
Minimum	-24.34%	-9.23%	-15.11%	-27.58%	-24.41%	-13.24%
Maximum	26.90%	17.33%	9.57%	31.05%	24.57%	12.53%

This table reports summary statistics of returns on equal-weighted (Panels A and B) and signal-weighted (Panel C) long/short carry trade portfolios over 1973:01 to 2017:06. Each portfolio is formed according to the yield on the investment vehicle and rebalanced each month (Panel A) or each December (Panels B and C). The equal-weighted portfolios go long currencies with the highest one-third of the yields and go short currencies with the lowest one-third of the yields. The signal-weighted portfolios go long currencies with above average yields and go short currencies with below average yields, such that all positive weights sum to one and all negative weights sum to negative one. Minimum and maximum values are one-month holding period returns in Panel A, while all other values are annualized values.

Table 4: Correlations of Carry Trade Portfolio Returns

	Monthly EW Short-Rate	Monthly EW Long-Bond	Annual EW Short-Rate	Annual EW Long-Bond	Annual SW Short-Rate	Annual SW Long-Bond
Monthly EW Short-Rate	1.000					
Monthly EW Long-Bond	0.884	1.000				
Annual EW Short-Rate	0.943	0.902	1.000			
Annual EW Long-Bond	0.818	0.903	0.857	1.000		
Annual SW Short-Rate	0.930	0.882	0.954	0.833	1.000	
Annual SW Long-Bond	0.788	0.843	0.804	0.929	0.838	1.000

This table reports correlations between returns on various carry trade portfolio returns over the Modern Sample (1973-2017). Each portfolio is formed according to the yield on the investment vehicle and rebalanced each month ('Monthly') or each December ('Annual'). The equal-weighted ('EW') portfolio go long currencies with the highest one-third value of the yields and go short currencies with the lowest one-third value of the yields. The signal-weighted ('SW') portfolio go long currencies with above average yields and go short currencies with below average yields, such that all positive weights sum to one and all negative weights sum to negative one.

Table 5: Short Rate Carry Trade Over the Recent Centuries

		Sub-Periods					
	Whole Sample	1855-1879 Early Second Industrial Revolution	1880-1913 Classic Gold Standard Era	1914-1949 World War Era	1950-1972 Bretton Woods Era	1973-1998 Pre-Euro Floating Exchange Regime	1999-2017 Post-Euro Floating Exchange Regime
Average Returns	2.07%	2.80%	2.40%	-0.04%	2.06%	2.16%	4.30%
Volatility	8.61%	7.13%	2.00%	14.31%	2.88%	5.59%	10.90%
Sharpe Ratio	0.240	0.392	1.200	(0.003)	0.714	0.387	0.395
FX Returns	-1.34%	0.89%	0.17%	-2.53%	-0.98%	-4.53%	-1.02%
Vol (FX)	8.39%	6.89%	1.78%	13.86%	2.69%	5.57%	10.16%
Carry Returns	3.52%	1.83%	2.23%	2.58%	3.08%	7.22%	5.37%
Vol (Carry)	2.16%	0.71%	0.67%	0.74%	0.35%	2.11%	0.69%

This table decomposes returns on annually-rebalanced equal-weighted long-short short rate carry trade over the recent centuries. Each portfolio is formed according to the yield on the short rate, using the short rate as the investment vehicle, and rebalanced each December. Sample periods are split across major periods in history across columns. Average returns, volatilities and Sharpe ratios are computed within each sub-period. Total investment returns are also split into currency returns ('FX returns') and yields on short rates ('Yield'). Averages and standard deviations ('Vol') of component returns are computed within each sub-period.

Table 6: Long Bond Carry Trade Returns Over the Recent Centuries

		Sub-Periods						
	Whole Sample	1789-1854 Age of Revolution	1855-1879 Early Second Industrial Revolution	1880-1913 Classic Gold Standard Era	1914-1949 World War Era	1950-1972 Bretton Woods Era	1973-1998 Pre-Euro Floating Exchange Regime	1999-2017 Post-Euro Floating Exchange Regime
Average Returns	5.28%	13.30%	2.76%	2.47%	-1.42%	3.51%	2.27%	4.74%
Volatility	16.07%	25.63%	4.75%	3.68%	10.87%	4.37%	8.35%	10.42%
Sharpe Ratio	0.328	0.519	0.557	0.672	(0.131)	0.803	0.272	0.455
FX Returns	-1.67%	-0.41%	-0.90%	-0.23%	-4.59%	-0.68%	-5.28%	-0.46%
Vol (FX)	7.26%	8.67%	3.28%	1.95%	9.44%	2.26%	6.02%	9.69%
Carry Returns	4.79%	8.40%	3.16%	1.87%	2.43%	2.86%	6.11%	4.62%
Vol (Carry)	4.10%	5.69%	1.27%	0.78%	0.78%	0.43%	1.57%	0.88%
Cap Gains	2.38%	5.51%	0.52%	0.86%	0.89%	1.44%	2.26%	0.83%
Vol (Cap Gains)	11.57%	20.52%	3.16%	2.11%	3.83%	3.45%	4.76%	4.23%

This table decomposes returns on annually-rebalanced equal-weighted long-short long bond carry trade over the recent centuries. Each portfolio is formed according to the yield on the long bond, using the long bond as the investment vehicle, and rebalanced each December. Sample periods are split across major periods in history across columns. Average returns, volatilities and Sharpe ratios are computed within each sub-period. Total investment returns are also split into currency returns ('FX returns'), yields on long bonds ('Yield'), and capital gains on long bonds ('Cap Gains'). Averages and standard deviations ('Vol') of component returns are computed within each sub-period.

Table 7: Robustness of Short Rate Carry Trade

	Whole Sample	Sub-Periods: 1855-1879 Early Second Industrial Revolution	1880-1913 Classic Gold Standard Era	1914-1949 World War Era	1950-1972 Bretton Woods Era	1973-1998 Pre-Euro Floating Exchange Regime	1999-2017 Post-Euro Floating Exchange Regime
Panel A: Signal-Weighted Portfolio Returns							
Average Returns	2.14%	3.13%	2.62%	-0.79%	2.34%	2.15%	5.48%
Volatility	9.52%	8.06%	2.65%	15.56%	2.80%	6.05%	11.98%
Sharpe Ratio	0.225	0.389	0.988	(0.051)	0.836	0.355	0.458
Panel B: Panel Regression Coefficients							
$\hat{\beta}^{\text{Panel}}$	0.367**	0.155	0.731**	-0.290	0.651**	0.311*	0.823**
	(0.092)	(0.298)	(0.069)	(0.484)	(0.137)	(0.124)	(0.117)
Panel C: Fama-MacBeth Regression Coefficients							
$\hat{\beta}^{\text{FM}}$	0.308**	0.109	0.708**	-0.342	0.624**	0.310**	0.750**
	(0.117)	(0.249)	(0.091)	(0.461)	(0.093)	(0.086)	(0.211)

This table shows the robustness of short rate carry trade. Sample periods are split across major periods in history across columns. Panel A shows the returns on annually-rebalanced signal-weighted long-short short rate carry trade. Each portfolio is formed according to the yield on the short rate, using the short rate as the investment vehicle, and rebalanced each December such that portfolio weights are proportional deviations from cross-sectional means. Average returns, volatilities and Sharpe ratios are computed within each sub-period. Panel B shows estimates from panel regressions with interaction terms for sub-periods, as described in Equation (20). Standard errors are shown in parenthesis and are two-way clustered by time and by currency. Panel C provides estimates from Fama and MacBeth (1973) regressions for each sub-period, with Newey-West standard errors. Estimates of constant terms are not shown. Standard errors are shown in parenthesis and are two-way clustered by time and by currency. Double asterisk (**), asterisk (*) and plus (+) represent statistical significance at the 99%, 95%, and 90% confidence levels, respectively.

Table 8: Robustness of Long Bond Carry Trade

	Whole Sample	Sub-Periods: 1789-1854 Age of Revolution	1855-1879 Early Second Industrial Revolution	1880-1913 Classic Gold Standard Era	1914-1949 World War Era	1950-1972 Bretton Woods Era	1973-1998 Pre-Euro Floating Exchange Regime	1999-2017 Post-Euro Floating Exchange Regime
Panel A: Signal-Weighted Portfolio Returns								
Average Returns	11.25%	29.19%	4.74%	5.06%	0.62%	6.50%	2.60%	6.66%
Volatility	37.54%	64.20%	9.78%	8.97%	15.90%	8.28%	9.76%	14.23%

This table examines robustness of dollar carry trade over the recent centuries. Sample periods are split across major periods in history across columns. Panel A shows the returns on annually-rebalanced equally-weighted dollar carry trade using short rates. Average returns, volatilities and Sharpe ratios are computed within each sub-period. Panel B shows the returns on annually-rebalanced equally-weighted dollar carry trade using long bonds. Panel C shows estimates from panel regressions with interaction terms for sub-periods, as described in Equation (20), for the short rate sample and for the long bond sample. Estimates of constant terms are not shown. Standard errors are shown in parenthesis and are two-way clustered by time and by currency. Double asterisk (**), asterisk (*) and plus (+) represent statistical significance at the 99%, 95%, and 90% confidence levels, respectively.

Table 10: Currency Momentum Trade Over the Recent Centuries

		Sub-Periods						
	Whole Sample	1789-1854 Age of Revolution	1855-1879 Early Second Industrial Revolution	1880-1913 Classic Gold Standard Era	1914-1949 World War Era	1950-1972 Bretton Woods Era	1973-1998 Pre-Euro Floating Exchange Regime	1999-2017 Post-Euro Floating Exchange Regime

This table examines robustness of currency momentum trade over the recent centuries, based on FX returns over the past twelve months. Sample periods are split across major periods in history across columns. Panel A shows the returns on monthly-rebalanced equally-weighted currency momentum trade using short rates. Average returns, volatilities and Sharpe ratios are computed within each sub-period. Panel B shows the returns on monthly-rebalanced equally-weighted currency momentum trade using long bonds. Panel C shows estimates from panel regressions with interaction terms for sub-periods, as described in Equation (20), for the short rate sample and for the long bond sample. Estimates of constant terms are not shown. Standard errors are shown in parenthesis and are two-way clustered by time and by currency. Double asterisk (**), asterisk (*) and plus (+) represent statistical significance at the 99%, 95%, and 90% confidence levels, respectively.

Table 11: Currency Reversal (Value) Trade Over the Recent Centuries

		Sub-Periods

This table examines robustness of currency reversal (value) trade over the recent centuries, based on FX returns over the past 5 years. Sample periods are split across major periods in history across columns. Panel A shows the returns on annually-rebalanced equally-weighted currency reversal trade using short rates. Average returns, volatilities and Sharpe ratios are computed within each sub-period. Panel B shows the returns on annually-rebalanced equally-weighted currency reversal trade using long bonds. Panel C shows estimates from monthly panel regressions with interaction terms for sub-periods, as described in Equation (20), for the short rate sample and for the long bond sample. Estimates of constant terms are not shown. Standard errors are shown in parenthesis and are two-way clustered by time and by currency. Double asterisk (**), asterisk (*) and plus (+) represent statistical significance at the 99%, 95%, and 90% confidence levels, respectively.

Table 12: Currency Term Spread (Slope) Trade Over the Recent Centuries

	1855-1879 Early Second Industrial Rev.	1880-1913 Classic Gold Standard Era	1914-1949 World War Era	1950-1972 Bretton Woods Era	1973-1998 Pre-Euro Floating Exchange Regime	1999-2017 Post-Euro Floating Exchange Regime

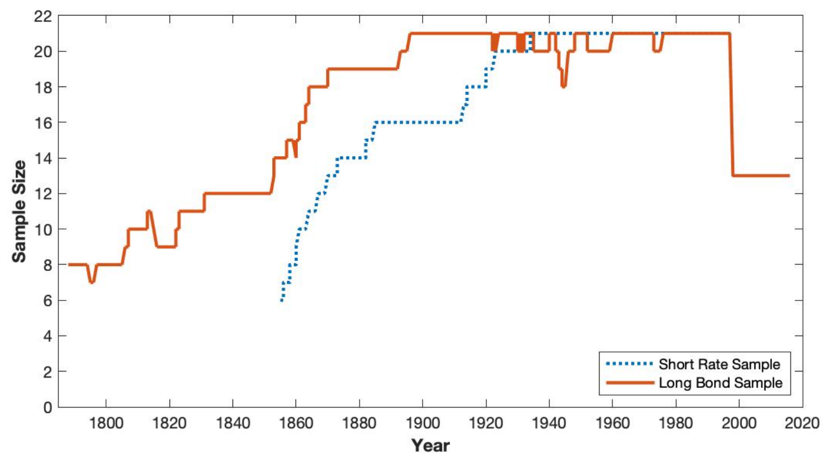
Spread	(0.052)	(0.510)	(0.160)	(0.319)	(0.114)	(0.377)

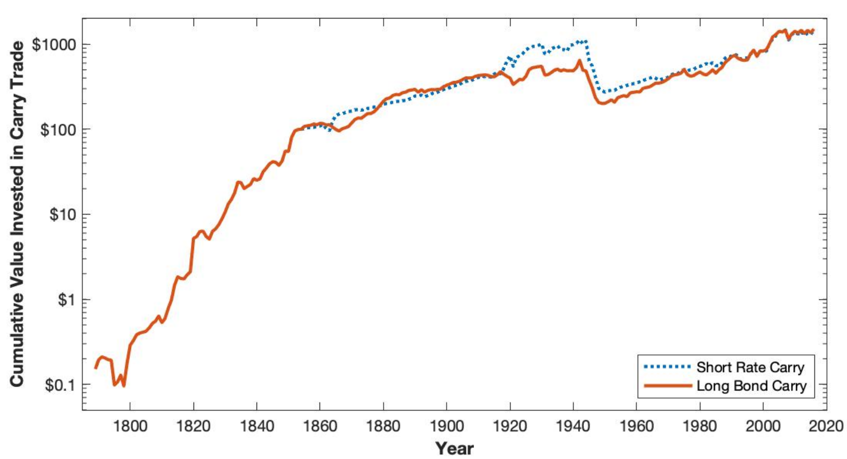
This table examines robustness of currency term spread (slope) trade over the recent centuries, based on the term spread. Sample periods are split across major periods in history across columns. Panel A (B) shows the returns on annually-rebalanced equally-weighted currency yield curve slope trade using short rates (long bonds). Panel C shows the returns on annually-rebalanced equally-weighted currency yield curve slope trade that goes long long bonds and short short rates (long-short spread). Panel D shows estimates from monthly panel regressions with interaction terms for sub-periods, as described in Equation (20). Estimates of constant terms are not shown. Standard errors are shown in parenthesis and are two-way clustered by time and by currency. Double asterisk (**), asterisk (*) and plus (+) represent statistical significance at the 99%, 95%, and 90% confidence levels, respectively.

Figure 1: Number of Currencies Used



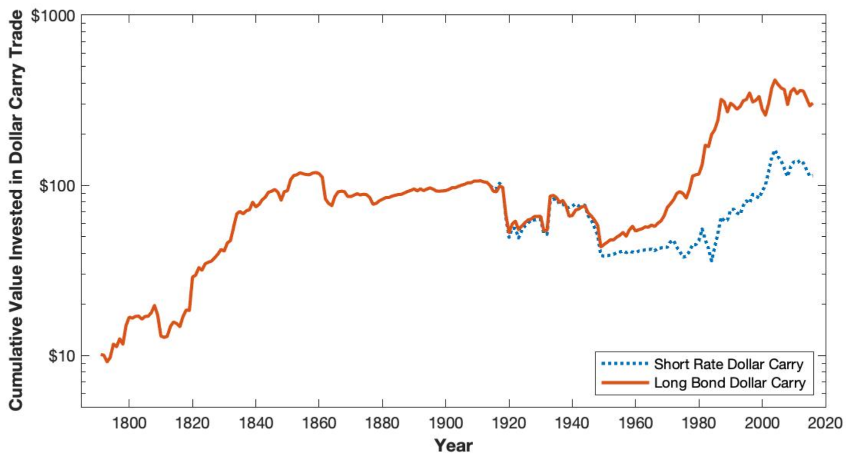
This plot shows the number of observations available in each of my samples. In addition to currency returns, the short rate sample uses short-term interest rates and the long bond sample uses long-term interest rates. For the short rate sample, data starts on 1854:01, and for the long bond sample, data starts on 1788:09. Data ends on 2017:06 in both samples.

Figure 2: Cumulative Returns on the Carry Trade



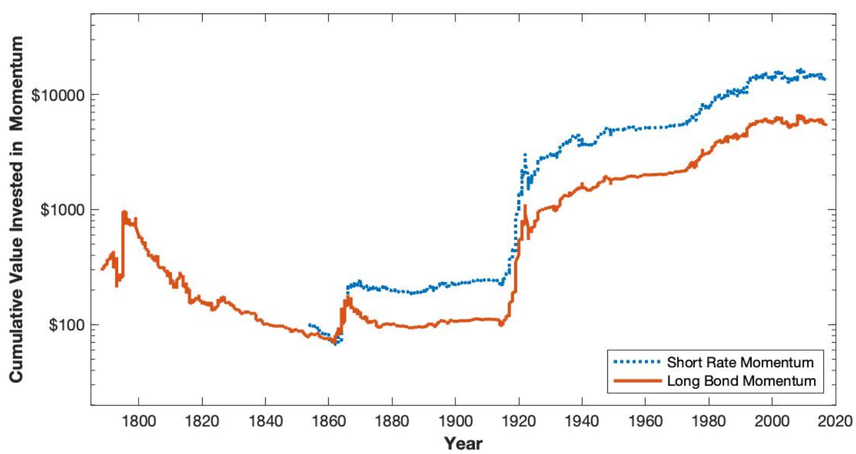
This plot shows the cumulative returns on long/short carry trade returns, normalized to $100 investment made in 1854. Each portfolio is formed according to the yield on the investment vehicle and rebalanced each December ('Annual'). The equal-weighted portfolios go long currencies with the highest one-third value of the yields and go short currencies with the lowest one-third value of the yields.

Figure 3: Cumulative Returns on the Dollar Carry Trade



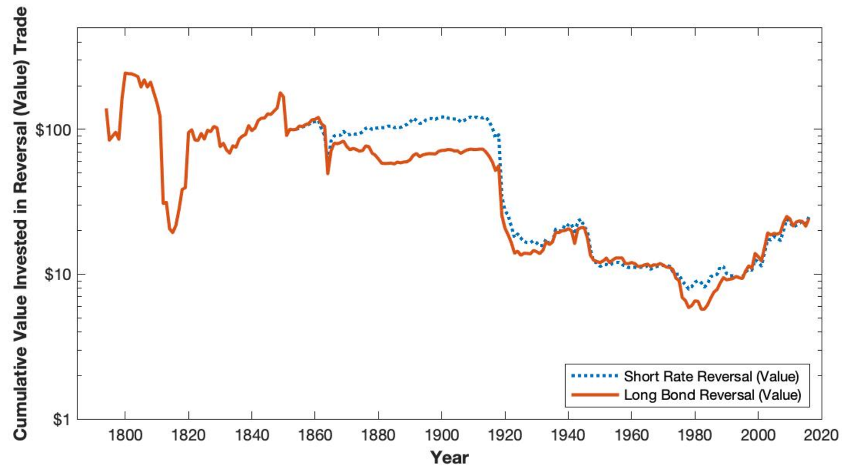
This plot shows the cumulative returns on the dollar carry trade returns normalized to $100 investment made in 1914. The dollar carry trade portfolio goes long (short) the US dollar (USD) when the yield on the USD investment instrument is greater (less) than the average of all other currencies and goes short (long) the equal-weighted portfolio of all other currencies.

Figure 4: Cumulative Returns on Currency Momentum



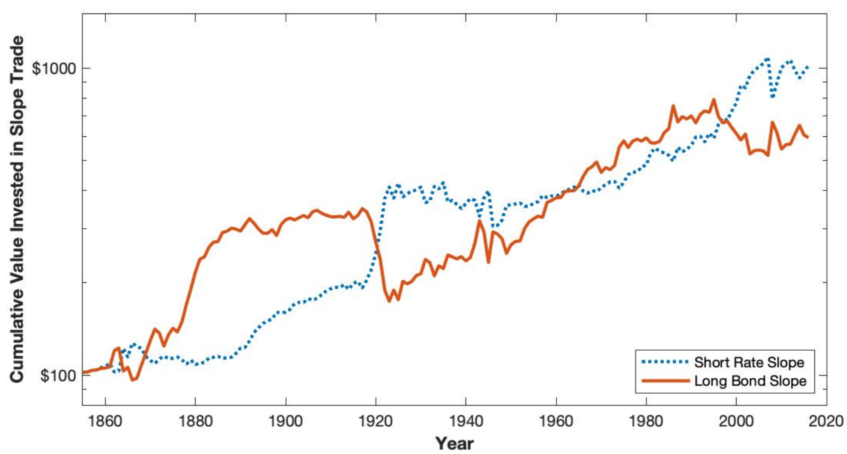
This plot shows the cumulative returns on long/short currency momentum returns normalized to $100 investment made in 1854. Each portfolio is formed according to FX returns over the past twelve months and rebalanced monthly. The equal-weighted portfolios go long currencies with the highest one-third value of past FX returns and go short currencies with the lowest one-third value of past FX returns.

Figure 5: Cumulative Returns on Currency Reversal (Value)



This plot shows the cumulative returns on long/short currency reversal (value) returns normalized to $100 investment made in 1854. Each portfolio is formed according to FX returns over the past 5 years and rebalanced annually each December. The equal-weighted portfolios go long currencies with the highest one-third value of past FX returns and go short currencies with the lowest one-third value of past FX returns.

Figure 6: Cumulative Returns on Term Spread (Slope) Trade



This plot shows the cumulative returns on long/short currency investment returns based on the yield term spread (slope) normalized to $100 investment made in 1854. Each portfolio is formed according to the slope of the yield curve and rebalanced annually each December. The equal-weighted portfolios go long currencies with the highest one-third value of the term spread and go short currencies with the lowest one-third value of the term spread.
